

ABSTRACT

BARCIO, SARAH ANN. Thermally Responsive Surfaces for Tissue Engineering and Apparel Applications. (Under direction of Dr. Marian G. McCord.)

Thermally responsive surfaces were created by grafting poly (N-isopropylacrylamide) (pNIPAM) onto polyester (PET) film and fabric using atmospheric pressure plasma treatment, which provided a quick, simple means of grafting that sufficiently sterilized the samples for cell culture. Grafting was achieved by a two-step process of surface activation with atmospheric pressure plasma followed by exposure of the substrate to a monomer solution in the presence of atmospheric pressure plasma. The plasma exposure time and monomer solution volume were optimized using cell culture studies. The graft was characterized by surface analysis techniques and cell culture studies. Contact angle measurements at different temperatures verified the thermally responsive nature of the graft on the PET film and fabric. Atomic force microscopy (AFM) was used to examine the surface topography and the effects of an aqueous environment on the surface. Scanning electron microscopy (SEM) was also used to examine the surface of the films and fabrics and to confirm the presence of the pNIPAM. AFM images showed the surface become significantly rougher and more variable when placed in water as the polymer chains became hydrated and a gel structure formed. The decrease in surface roughness seen with the grafted film and the SEM images confirm the graft coating the untreated film. The graft thickness on the PET film was found to be between 30 and 100 nm with AFM measurements. An acid dye test verified the presence of the graft on the filtration fabric. Cell culture studies were completed using human epidermal keratinocytes (HEKs), human lung fibroblasts (HFLs), and human

hepatocellular carcinoma (Hep G2) cells to demonstrate thermally modulated cellular adhesion, growth and detachment on the films and fabrics. Viable cell sheets were successfully released from atmospheric plasma grafted pNIPAM on polyester film. Although no detachment was achieved with the grafted PET fabric, the treated fabrics could potentially be useful for tissue engineering scaffolds in bioreactors or for large-scale cell sheet engineering.

Thermally responsive textiles were created using coat- and spray-grafting of pNIPAM onto woven cotton, nylon, and polyester with atmospheric pressure plasma treatment. Fourier transform infrared spectroscopy (FTIR) was used to examine the surface chemistry and confirm the presence and washfastness of the grafts produced from the two methods. Vertical wicking tests showed an increase in wettability with increasing temperature. Coat-grafted fabrics had the greatest resistance to wicking, and spray-grafted fabrics had the greatest wicking. An acid dye test also confirmed the presence of the graft showing the greatest uniformity and washfastness from the coat-grafting method. Once fully characterized, these fabrics could be used as responsive textiles for apparel applications.

Dr. Nancy Monteiro-Riviere
Member of Advisory Committee

Dr. Marian McCord
Chair of Advisory Committee

DEDICATION

This work is dedicated to my parents, sister, and fiancé who have been so supportive and encouraging throughout this whole experience. I love you guys!

BIOGRAPHY

Sarah Ann Barcio was born April 16, 1982 in Racine, Wisconsin to Gayle and Dave Barcio. She also has a younger sister Rachel and fiancée Chris Boyd. Sarah completed her B.S. degree in Polymer and Textile Chemistry with a minor in Bioengineering in December of 2003 from Clemson University. She began a M.S. in Biomedical Engineering in August of 2004 at North Carolina State University.

ACKNOWLEDGEMENTS

This work could have only been completed with the assistance of many people. First, I would like to thank my committee chair, Dr. Marian McCord, for her ideas, support, and guidance. I would also like to thank Dr. Mohamed Bourham for his help with the plasma and for the use of the machine and Dr. Nancy Monteiro-Riviere for her suggestions and help with the cell culture studies. In addition, I would like to thank Dr. Phil Sannes for generously allowing me to use his facilities and materials and Dr. Haskell Beckham for analysis of samples and insight with my fabric studies.

I am grateful for the assistance and expertise of Al Inman, Donna Newman, and Dr. Susan Bernacki, who were all indispensable with the cell culture studies and troubleshooting. I would also like to thank Birgit Anderson, Chuck Mooney, Roberto Garcia, Julie Gentry, Jeff Krauss, and Dr. Kirill Efimenko for help with testing and training for the characterization of my surfaces. Dr. Jan Genzer graciously allowed me to use his lab and equipment for important testing as well. I would also like to thank Dr. Michelle Wall and Dr. Elizabeth Lobo for introducing me to cell culture and giving me invaluable skills for use in my project.

Finally, I would like to thank all the undergraduates who helped me with testing and preparing samples along the way, Xiaoling Wang for her direction and previous work, and Carrie Cornelius for her support and suggestions throughout this whole process.

1. INTRODUCTION

Responsive polymers exhibit functional changes in response to a stimulus giving them dual and reversible properties. These polymers have received much attention for many applications including biotechnology and smart textiles. Particularly attractive responsive polymers are those stimulated by temperature. They are easy to control and allow for careful modulation of the property changes of the polymer. Poly (N-isopropylacrylamide) (pNIPAM) is a thermally responsive polymer that displays a phase change at 32°C, which is between room and body temperatures.^[1] This transition temperature allows it to be useful for biological applications such as drug delivery, bioseparation, biosensors, gene delivery, and cell sheet engineering.^[5] Above 32°C in water, the polymer becomes dehydrated and hydrophobic allowing cell adhesion; when the temperature is dropped below 32°C, the polymer chains rapidly hydrate and cells detach from the surface.^[37] The potential for releasing cell sheets with intact junctions is important for the future of tissue engineering as it does not introduce any of the problems with current approaches such as compliance mismatch, the inflammatory response, and the inability to repair large areas of tissue.

Grafting pNIPAM onto other substrates imparts the thermoresponsiveness to the substrate surface. PNIPAM grafting can be achieved through reactions induced by chemical reagents, UV, electron beam irradiation, γ -irradiation, and plasma treatment. Each method has advantages and disadvantages, but atmospheric plasma treatment is a novel method of grafting pNIPAM that is quick, easy, and can be used in a continuous process.

This work evaluates atmospheric plasma grafting of pNIPAM on polyester film and optimization of treatment parameters with cell culture studies intended as a model for cell attachment/detachment on polyester filtration fabric. It also examines two methods of pNIPAM grafting on woven cotton, nylon, and polyester fabrics through surface characterization and wettability testing. The goals of the research are to create thermally responsive textile substrates for tissue culture that allow for control of the attachment and release of individual cells or cell sheets and provide new surfaces for large-scale cell sheet engineering or tissue engineering scaffolds in bioreactors.

2. LITERATURE REVIEW

2.1. Thermoresponsive Polymers

“Smart” polymers are those that demonstrate reversible sharp property changes in response to environmental cues such as pH, electric field, light, and temperature.

Temperature is one of the most commonly used stimuli in responsive polymers due to the ease of control. There are many thermoresponsive polymers used for drug delivery and biotechnology applications. However, poly (N-isopropylacrylamide) (pNIPAM) is one of the most widely studied thermoresponsive polymers because of its acute phase transition near human body temperature. In water, pNIPAM undergoes a phase separation with an increase in temperature at a lower critical solution temperature (LCST) of 32°C. PNIPAM chains hydrate to form an expanded, hydrophilic structure in water when the solution temperature is below its LCST and dehydrate to form a compact, hydrophobic structure when heated to above the LCST.^[1] This behavior is shown in Figure 2.1 using wettability and contact angle measurements.

It has been found that enzymatic and mechanical detachment can disrupt the cell membrane and cause a change in cellular activity.^[15]

As mentioned above, pNIPAM grafted surfaces have already been used extensively for cell culturing being used with urothelial, vascular smooth muscle, retinal, and lung cells to list a few.^[16-19] This has led it to be looked at for tissue engineering and more specifically cell sheet engineering use. Traditional methods for tissue engineering are based on isolated cell suspensions or biodegradable scaffolds.^[6] These two methods have shown limited success and improvement of them has been slower than expected leaving room open for other options. Okano's group recently identified cell sheet engineering as another option.^[6] This type of engineering is advantageous because it yields cell sheets that retain their native extracellular matrix, which is responsible for the intrinsic adhesion.^[2] Tissue reconstruction can be performed with different types of cell sheets. Single cell sheets can be used for the cornea; and multilayer sheets can be used in the heart as shown in Figure 2.6.

treatment induces significant changes in the roughness of a polyester film substrate due to etching.^[26] With these two things in mind, we can account for the changes in the appearances of the surface with each treatment.

The results from the dry and wet scans are shown below in Figure 4.8. Plasma pre-treatment has an obvious effect on the surface roughness as indicated by Figure 4.8 A and B. The plasma pretreated film shown in B showed a reduction in the mean-square roughness (RMS) from 11.2 to 7.72 nm when compared to untreated film. Grafting on top of the plasma pre-treated films induces further changes in surface topography (Figure 4.8 C) but no significant change in surface roughness.

When placed in water at room temperature, the surface becomes significantly rougher and more variable. At 37°C, the surface shows a large increase in roughness. Phase images of the grafted polymer reveal a relatively uniform surface for the dry graft, and an orange peel type phase variation on the wet graft surface. The nanometer-size dots in the wet phase image (F) may be the result of changes in the polymer crosslink density over the surface.^[5,27] The surface transformation in the hydrated state leads to a change in average roughness (Ra) from 4.72 ± 0.71 nm (dry) to 5.90 ± 1.51 nm (wet, 24°) and 12.24 ± 5.32 nm (wet, 37°). This can be seen in Figure 4.9. The RMS roughness also increased from 7.15 ± 1.52 nm (dry) to 9.47 ± 3.32 nm (wet, 24°) and 31.65 ± 13.22 nm (wet, 37°). This increase in roughness was expected and consistent with findings of Cheng et. al.^[5]

and grafted fabric samples were tested. The cells were checked four days after seeding and kept at room temperature to observe cell detachment. Once again, the cells were difficult to distinguish, so Coomassie Blue was used to stain the cells prior to viewing. The cells were approximately 90% confluent on the surrounding insert, but it is difficult to determine the exact confluency on the filtration fabrics. Based on the dye patterns, the untreated and plasma pretreated fabrics both displayed 60% confluency or higher. The elongated shape and nuclei of the fibroblasts were noticeable on these surfaces as well. The grafted fabric showed cell growth to be approximately 50% confluent. However since we were unable to view the cells before staining and washing, it was possible that some cells were washed off during this process. The unseeded fabrics tested for staining with the Coomassie blue both showed little or no dye pick-up. This finding further confirms the presence of cells on the fabrics. These results demonstrate the ability of the cells to grow on the fabric. Figure 4.21 shows the results of the cell culture study with HFLs on the fabric.

4.3.5. Surface Morphology

Scanning electron microscopy was used to examine the plasma treated and grafted surfaces and to characterize the uniformity of the grafted pNIPAM. The SEM images are shown in Figure 4.22. The grafted polymer was not readily apparent on the surfaces of the fabrics, although the grafted fabric filaments do appear smoother as though the pNIPAM filled in the surface blemishes. However, as suspected, the thickness of the graft was insufficient to be detected using SEM.

Figure 4.22: SEM results of original (A), plasma pretreated (B), and grafted (C) fabric.

4.3.6. Graft Uniformity

Although the contact angle measurements on the grafted fabric demonstrated the thermoresponsiveness of the pNIPAM, further confirmation of the uniformity of the graft was necessary to ensure efficiency of the plasma treatment. A simple dye test using an acid dye, which is known to color the amino end groups of nylons, was used since pNIPAM is an amide.^[29] A piece of untreated, plasma pretreated, and grafted fabric was tested. The results are shown in Figure 4.23.

Figure 4.23: Acid dye test results from untreated (A), plasma pretreated (B), and grafted PET filtration fabric.

The blue coloring on the grafted fabric was clearly visible and was not seen on the untreated and plasma pretreated fabrics. However, the dye does look darker in some spots possibly indicating a thicker graft in those areas. This test confirmed that the pNIPAM was successfully grafted to the filtration fabric in a fairly uniform manner with some patchy areas.

4.3.7. Cell Growth, Detachment, and Viability with Hep G2 Cells

A third test for growth was performed using Hep G2 cells. This time grafted fabric pieces were placed on the bottom of a non-tissue culture treated 6-well PS plate, and the cells were seeded on top of the fabric to be observed with an inverted microscope.

Because of previous problems viewing the cells, a fluorescent nuclear stain was used to view cell growth and detachment; and a fluorescent assay was performed to confirm the viability of the cells on the fabric. The fabric fluoresces naturally but not enough to present a problem when viewing the cells.

For the viability test, the cells were observed one, two, and six days after seeding. The results of the viability test are shown in Figures 4.24 and 4.25. The cells proliferated well on the fabric. The cells stained after only 1 day of incubation clearly preferred growing on the natural grooves in the fabric as seen in Figure 4.24 A and B. However after 2 and 6 days of incubation, the cells spread out over the surface of the fabric and grew to at least 60% confluency. A small number of dead cells were seen on each day, but overall the cells attached and proliferated successfully on the PET filtration fabric.

Figure 4.24: Live cells seen with the viability test on grafted PET filtration fabric seeded at a density of 20,000 cells after 1 (A), 2 (C), and 6 (E) days and seeded at a density of 40,000 cells after 1 (B), 2 (D), and 6 (F) days.

Even with the fluorescent stain, clear visualization of the cells on the fabric was difficult. The cells clearly proliferated well on the grafted fabric; but after no detachment was observed after cooling for 90 minutes, the cells were examined further. A closer look at the cells revealed possible growth in the pores or between the twill weave of the fabric shown in Figure 4.27. The circled areas highlight cells that come into or out of focus with the change in focal point on the fabric. This suggests cells are growing in both focal planes.

Figure 4.27: Possible cell growth between the weave or in fabric pores shown with focal point changes on same area in two parts of the fabric at 20x.

Lee et al. found that a pore size equal to or greater than 5 μm hindered the adhesion and growth of fibroblasts on polycarbonate membranes suggesting the difficulties of growing

cells on the PET filtration fabric.^[30] Although the Hep G2 cells and HFLs grew well on the fabric, it does pose questions about the effects of the large pore size. Since the pores are larger, they allow for cells to grow around the edge of the filament and into the pore.^[31] If the cells are growing in the pore space, the unsuccessful detachment of the cells is likely due to two reasons. First, cells growing on edges must apply a larger adhesive force to hang on than those on a flat surface.^[30] Second, it is possible that there is a reduction in the amount of pNIPAM grafted on the inner sides of the filaments due to inability of the plasma to efficiently access those areas and a reduction in the monomer solution volume as it flows through the pores during the coating procedure.^[4] It has been found that the monomer solution solvent type and concentration has an effect on the grafting rate of a porous membrane.^[35,52] Although it was found that methacrylate can be grafted into submicron pores, this was not evident in our fabric when viewed with SEM; and the pores of our fabric may be too large for the polymer chains to bridge.^[52] If the cells are growing within the weave of the fabric, the unsuccessful detachment may be due to the large variations in the surface and subsequent irregular cell sheet formation or entrapment of cells between the filaments and thus attachment of cells to ungrafted areas of the fabric. However, it still remains unclear as to why the cells did not detach. Further characterization of the grafted fabric needs to be examined; and a flatter fabric with a smaller pore size should be tested to evaluate the effects of the weave and pore size on cell attachment and detachment.

4.4.1. Surface Chemistry

Fourier Transform Infrared Spectroscopy (FTIR) produces information on the chemical composition of a specific chemical species. It is a very powerful tool used to identify specific chemical bonds simply by interpreting the infrared absorption spectrum. The characteristic peaks that correspond to the chemical structure of pNIPAM should be observed at 1386 cm^{-1} (methyl group deformation), 1458 cm^{-1} ($-\text{CH}_3$ and $-\text{CH}_2-$ deformation), 1540 cm^{-1} (secondary amide N-H stretching), 1650 cm^{-1} (secondary amide C=O stretching), 2970 cm^{-1} ($-\text{CH}_3$ asymmetric stretching), and 3300 cm^{-1} (secondary amide N-H stretching).^[1,3] The test was done to give an indication of the amount of pNIPAM being grafted on the fabrics and compare the washfastness of the graft from the two methods. The results for the cotton fabrics are shown in Figure 4.28.

Figure 4.28: FTIR spectra of the cotton fabrics.

peak occurring at 2970 cm^{-1} was used to evaluate grafting. This peak appeared only on the coat-grafted nylon demonstrating the effectiveness of the coat method. The small peak was not visible on coat-grafted and washed nylon. However since a decrease in absorbance was seen with the washed cotton fabrics, it is likely that the already small peak was diminished on the washed nylon sample. Once again, the spray-grafted fabrics did not show the characteristic pNIPAM peak and mimicked the untreated nylon spectra. This was likely due to the thinness of the graft using the spray method.

The results for the polyester fabrics are shown in Figure 4.30.

Figure 4.30: FTIR spectra of the polyester fabrics.

The characteristic peaks that correspond to the chemical structure of pNIPAM were seen at 1458 cm^{-1} , 1540 cm^{-1} , and 1650 cm^{-1} for the coat-grafted and spray-grafted polyester indicating the successfulness of both methods. The 2970 cm^{-1} peak seen on the coat-

grafted fabric was also apparent on the coat-grafted and washed fabric although at a lower absorbance band. However, it does confirm the washfastness of the coat-grafted polyester fabrics. The spray-grafted and washed fabric did not show any of the characteristic pNIPAM peaks and mimicked the spectra of the untreated polyester. This result could be due to the reduced monomer solution volume used and thinness of the graft with the spray method or an indication of insufficient washfastness.

Overall, the spectra from the coat-grafted fabrics indicated successful grafting of pNIPAM onto cotton, nylon, and polyester and moderate washfastness. The differences seen between the spectra of the three fabrics likely were dependent on the wet-pickup of each type of fabric and its affinity for the monomer solution. Thus, the best grafting method is dependent on which type of fabric is desired.

4.4.2. Effects of Temperature on Wettability and Wicking

PNIPAM has been shown to change wettability with temperature. When grafted on textiles, the known wettability of the particular fabric should be altered as well. To examine the effects of the graft on the fabrics' wettability and wicking properties, the spray- and coat-grafted fabrics were evaluated with a vertical wicking test using cool (20°C) and warm (50°C) water. Untreated, plasma pretreated, grafted, and washed cotton, nylon, and polyester fabrics were tested. The tests were repeated four times and examined at 5, 15, and 30 minutes after immersion. The results for the coated and sprayed fabrics are shown in Figures 4.31, 4.32, and 4.33 and are reported in percentages since all of the samples were not exactly the same length.

Figure 4.31: Average percent of total wetting after 5 minutes with cool water (blue) and warm water (purple).

5. CONCLUSION

Thermally responsive pNIPAM was successfully grafted onto polyester film and filtration fabric. The atmospheric pressure plasma treatment provided a quick, simple means of grafting, and it sufficiently sterilized the samples for cell culture. The treatment parameters for grafted polyester films were optimized with cell culture studies with HEKs and found to be 3 minute plasma pretreatment, 5 minute plasma post-treatment, and $15.4 \mu\text{L}/\text{cm}^2$ of the monomer solution. The optimally grafted PET film was then characterized. Contact angle measurements confirmed the phase change of the pNIPAM by showing an increase in hydrophobicity with an increase in temperature. AFM images show the surface becomes significantly rougher and more variable when placed in water as the polymer chains become hydrated and gel structure forms. The decrease in surface roughness seen with the grafted film and the SEM images confirms the graft coats the untreated film filling in the natural cavities. The graft thickness was found to be between 30 and 100 nm with AFM measurements. Cell proliferation and detachment with HFLs demonstrates the ability of the surface to be used with various cell types and the structure transformation upon lowering the temperature.

Characterization of the PET filtration fabric with contact angle measurements also confirmed the phase change and successful grafting of pNIPAM. Although FTIR and SEM did not show the graft on the fabric, they were evidence of the thin graft produced with atmospheric plasma treatment. The uniformity and further proof of grafted pNIPAM on the fabric was seen with acid dye testing. Cell culture studies with HFLs and Hep G2

cells exhibit the cellular proliferation on the grafted fabric, although no detachment was observed.

Coat- and spray-grafted woven cotton, nylon, and polyester were compared and characterized. FTIR spectra from the coat-grafted fabrics indicated successful grafting of pNIPAM onto cotton, nylon, and polyester and moderate washfastness; spectra from the spray-grafted fabrics did not confirm grafting but could have resulted from a thin graft as seen with the filtration fabric and PET film. Vertical wicking tests showed an unexpected increase in wettability with increasing water temperature. They also showed that the coat-grafted fabrics had the greatest resistance to wicking and the washed spray-grafted fabrics had the greatest wicking. The acid dye test showed that the coat-grafted fabrics had the best washfastness and uniform graft, but the type of fabric and its properties seem to have an effect on the grafting method.

6. FUTURE RECOMMENDATIONS

Although this work sufficiently optimized the plasma parameters for polyester film and gave an idea about the characteristics of the pNIPAM coating being grafted onto different surfaces, further investigation into the following areas is necessary for utilization of the responsive textiles:

- Extensive force-displacement and thickness testing of the graft in fluid at varying temperatures to obtain a better understanding of how the polymer is changing at the transition and further characterize the graft produced with atmospheric plasma;
- Cell culture studies with a microporous fabric or a membrane with small pore size to facilitate detachment and less cell growth between the filaments;
- Facilitation of cell sheet detachment from grafted film to improve release mechanism;
- Continued cell culture studies with more cell types on grafted film to enhance the practicality of using grafted surfaces for many cell sheet engineering applications;
- Optimization of plasma parameters and experimentation with different gases and configurations;
- Characterization of grafted woven textiles;
- Improvement of the spray-grafting method to achieve greater washfastness and develop a thermoresponsiveness closer to that of bulk pNIPAM.
